## ABSTRACT :

A driver never runs by itself. It is similar to a library that is loaded for its functions to be invoked by a running application. It is written in C, but lacks a `main()` function. Moreover, it will be loaded/linked with the kernel, so it needs to be compiled in a similar way to the kernel, and the header files you can use are only those from the kernel sources, not from the standard `/usr/include`.

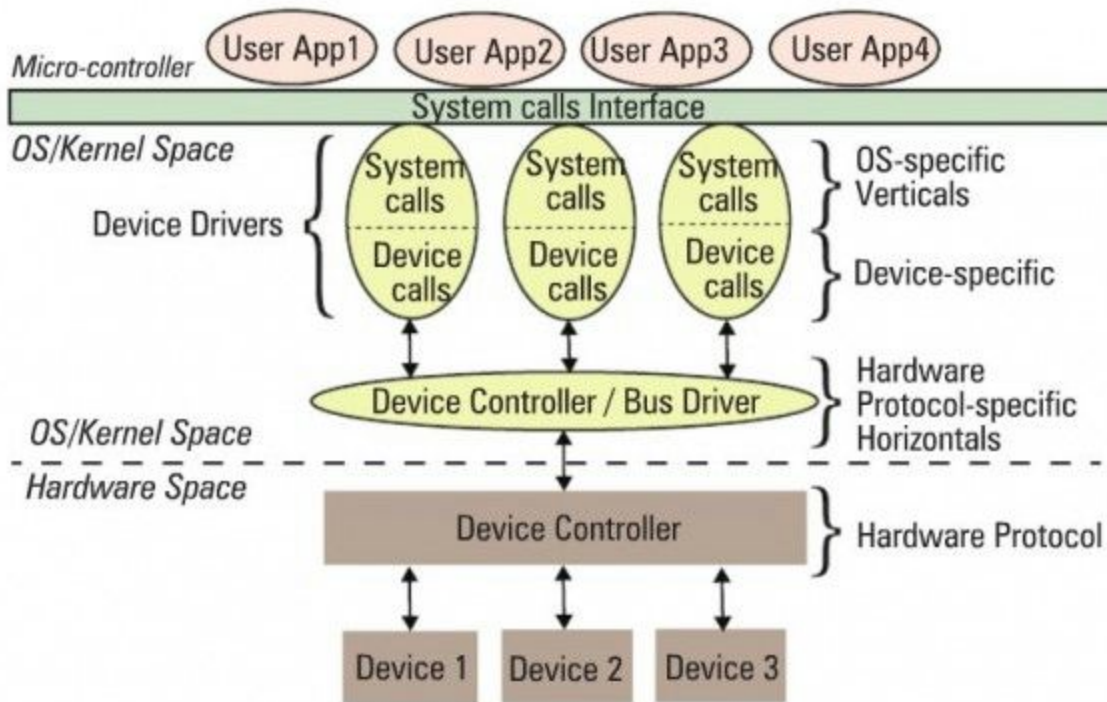

Kernel is that it is an object-oriented implementation in C, as we will observe even with our first driver. Any Linux driver has a constructor and a destructor. The module's constructor is called when the module is successfully loaded into the kernel, and the destructor when `rmmod` succeeds in unloading the module. These two are like normal functions in the driver, except that they are specified as the `init` and `exit` functions, respectively, by the macros `module_init()` and `module_exit()`, which are defined in the kernel header `module.h`.

# Introduction

A driver drives, manages, controls, directs and monitors the entity under its command. a specific piece of hardware could be controlled by a piece of software, known as device driver. Bus drivers provide hardware-specific interfaces for the corresponding hardware protocols, and are the bottom-most horizontal software layers of an operating system (OS). Over these sit the actual device drivers. These operate on the underlying devices using the horizontal layer interfaces, and hence are device-specific.

However, the whole idea of writing these drivers is to provide an abstraction to the user, and so, at the other “end”, these do provide an interface (which varies from OS to OS). In short, a device driver has two parts, which are: a) device-specific, and b) OS-specific.

**Dynamically loadable drivers** are more commonly called modules and built into individual files with a .ko (kernel object) extension. Every Linux system has a standard place under the root of the file system (/) for all the pre-built modules. They are organised similar to the kernel source tree structure, under /lib/modules/<kernel\_version>/kernel.

### \_\_init and \_\_exit

\_\_init and \_\_exit are not special keywords. Kernel C is just standard C with some additional extensions from the C compiler, GCC. Macros \_\_init and \_\_exit are just two of these extensions. However, these do not have any relevance in case we are using them for a dynamically loadable driver, but only when the same code gets built into the kernel. All functions marked with \_\_init get placed inside the init section of the kernel image automatically, by GCC, during kernel compilation; and all functions marked with \_\_exit are placed in the exit section of the kernel image.

the benefit of this is all functions with \_\_init are supposed to be executed only once during bootup (and not executed again till the next bootup). So, once they are executed during bootup, the kernel frees up RAM by removing them (by freeing the init section). Similarly, all functions in the exit section are supposed to be called during system shutdown.

Now, if the system is shutting down anyway, why do you need to do any cleaning up? Hence, the exit section is not even loaded into the kernel

# 1<sup>ST</sup> MODULE: USB device detection in Linux

Whether a driver for a USB device is there or not on a Linux system, a valid USB device will always be detected at the hardware and kernel spaces of a USB-enabled Linux system, since it is designed (and detected) as per the USB protocol specifications. Hardware-space detection is done by the USB host controller — typically a native bus device, like a PCI device on x86 systems. The corresponding host controller driver would pick and translate the low-level physical layer information into higher-level USB protocol-specific information. The USB protocol formatted information about the USB device is then populated into the generic USB core layer (the `usbcore` driver) in kernel-space, thus enabling the detection of a USB device in kernel-space, even without having its specific driver.

After this, it is up to various drivers, interfaces, and applications (which are dependent on the various Linux distributions), to have the user-space view of the detected devices. Figure 1 shows a top-to-bottom view of the USB subsystem in Linux.

So after plugging in the USB With **product id : 0951 and Vendor id : 1624**, `uas` and `usb_storage` gets loaded in the kernel space

```
nikita@nikita-pc:~$ lsusb

nikita@nikita-pc:~$ lsmod
Module                  Size  Used by
uas                     27255  0
usb_storage             66545  2 uas
ipt_MASQUERADE          12880  1
xt_conntrack            12760  1
ipt_REJECT              12541  2
xt_tcpudp               12884  4
iptable_filter          12810  1
```

so we removed these loaded modules using

- 1) `sudo rmmod uas`
- 2) `sudo rmmod usb_storage`

After this we need to make kernel module of our coded device driver. This is done by creating a `MAKEFILE` and using the command **make** as a super user on **pen.c**

This creates different file step by step till `pen.ko` is created. Files created are

- 1)Module.symvers
- 2)modules.order
- 3)pen.mod.c
- 4)pen.mod.o
- 5)pen.o
- 6)pen.ko

After this we need to register pen.ko with the kernel so as when the USB is connected to the Linux system by using the command **insmod pen.ko** as a **super user** ,

Using dmesg ,will show the kernel logs

[\*]Constructor of driver module is made incharge of it.

## 2<sup>ND</sup> MODULE: USB endpoints and their types

Depending on the type and attributes of information to be transferred, a USB device may have one or more endpoints, each belonging to one of the following four categories:

- **Control** — to transfer control information. Examples include resetting the device, querying information about the device, etc. All USB devices always have the default control endpoint point as zero.
- **Interrupt** — for small and fast data transfers, typically of up to 8 bytes. Examples include data transfer for serial ports, human interface devices (HIDs) like keyboards, mouse, etc.
- **Bulk** — for big but comparatively slower data transfers. A typical example is data transfers for mass-storage devices.
- **Isochronous** — for big data transfers with a bandwidth guarantee, though data integrity may not be guaranteed. Typical practical usage examples include transfers of time-sensitive data like audio, video, etc.

Additionally, all but control endpoints could be “in” or “out”, indicating the direction of data transfer; “in” indicates data flow from the USB device to the host machine, and “out”, the other way.

Technically, an endpoint is identified using an 8-bit number, the most significant bit (MSB) of which indicates the direction — 0 means “out”, and 1 means “in”. Control endpoints are bidirectional, and the MSB is ignored.

with access to the struct `usb_device` handle for a specific device, all the USB-specific information about the device can be decoded,

- Build the driver (`pen_info.ko` file) by running `make`.
- Load the driver using `insmod pen_info.ko`.
- Plug in the pen drive (after making sure that the `usb-storage` driver is not already loaded).
- Unplug the pen drive.
- Check the output of `dmesg` for the logs.

# 3<sup>RD</sup> MODULE: Data Transfer to and from USB Devices

USB, being a hardware protocol, forms the usual horizontal layer in the kernel space. And hence, for it to provide an interface to user-space, it has to connect through one of the vertical layers.

Also, we do not need to get a free unreserved character major number, but can use the character major number 180, reserved for USB-based character device files. Moreover, to achieve this complete character driver logic with the USB horizontal in one go, the following are the APIs declared in `<linux/usb.h>`:

```
int usb_register_dev(struct usb_interface *intf, struct usb_class_driver *class_driver);
```

```
void usb_deregister_dev(struct usb_interface *intf, struct usb_class_driver *class_driver);
```

, to achieve the hot-plug-n-play behaviour for the (character) device files corresponding to USB devices, these are instead invoked in the probe and disconnect callbacks, respectively.

The first parameter in the above functions is the interface pointer received as the first parameter in both probe and disconnect. The second parameter, `struct usb_class_driver`, needs to be populated with the suggested device file name and the set of device file operations, before invoking `usb_register_dev`. For the actual usage, refer to the functions `pen_probe` and `pen_disconnect` in the code listing of `pen_driver.c` below.

Moreover, as the file operations (write, read, etc.,) are now provided, that is exactly where we need to do the data transfers to and from the USB device. So, `pen_write` and `pen_read` below show the possible calls to `usb_bulk_msg()` (prototyped in `<linux/usb.h>`) to do the transfers over the pen drive's bulk end-points 0x01 and 0x82, respectively.

**Note :** That a pen drive belongs to a USB mass storage class, which expects a set of SCSI-like commands to be transacted over the bulk endpoints. So, a raw read/write as shown in the code

listing below may not really do a data transfer as expected, unless the data is appropriately formatted.

Commands that need to be followed are :

- Build the driver (pen\_driver.ko) by running make.
- Load the driver using insmod pen\_driver.ko.
- Plug in the pen drive (after making sure that the usb-storage driver is not already loaded).
- Check for the dynamic creation of /dev/pen0 (0 being the minor number obtained — check dmesg logs for the value on your system).
- Possibly try some write/read on /dev/pen0 (you most likely will get a connection timeout and/or broken pipe errors, because of non-conforming SCSI commands).
- Unplug the pen drive and look for /dev/pen0 to be gone.
